

**Device Comprising an Electrical Circuit Carried by a Carrier Element and  
Method for the Manufacture of Such a Device.**

**BACKGROUND OF THE INVENTION**

5           The present invention relates to a device comprising an electrical circuit carried by a carrier element, an electrically conductive structure being provided on a surface of the carrier element, and to a method for the manufacture of such a device.

10           Such a device is, for example, a component manufactured using the thin-film technique. Such a component may consist of:

- 15
- a plate-shaped carrier element generally referred to as the substrate and normally consisting of ceramics, silicon or glass,
  - an electrically conductive structure applied to the carrier element using the thin-film technique, strictly speaking to the surface of a specific side of the carrier element, wherein this electrically conductive structure can be of one or more layers, and wherein this electrically conductive layer can form:
    - 20       – strip conductors,
    - passive components, such as resistors, coils and capacitors,
    - active components, for example, transistors,
    - first contact points (pads) for creating a connection with components to be mounted on the carrier element, such as, for example, one or more semiconductor chips and/or additional or other components, and
    - 25       – second contact points (pads) for creating a connection with input and/or output terminals contained in the housing of the arrangement (for connection of the arrangement to other components of the system containing the arrangement),
    - 30       – components optionally mounted on the carrier element and connected with the first contact points, and
    - a housing enclosing the said components and comprising the already mentioned input and/or output terminals of the arrangement.

As is known, devices of that kind enable any desired electrical circuits to be accommodated in a relatively simple manner in very little space.

Such devices cannot be used for all applications however. For example, it is impossible, or possible only with disproportionately great effort, to construct an inductive sensor using such a device. Although the construction of the coils to be provided to detect magnetic fields would not present problems (this can be done by suitable construction and arrangement of the electrically conductive structure), the position of the second contact points already mentioned above and/or the course of the connecting leads connected thereto, normally in the form of bonding wires, to the input and/or output terminals of the arrangement, and possibly also the position of the input and /or output terminals, present difficulties. There are two reasons for this: on the one hand the environment of the part of the electrically conductive circuit forming the coil(s) must be free from electrically conductive materials (otherwise mirror-image currents impairing the function of the sensor can develop), and on the other hand the course of the connecting leads can impose constraints on the placement of the sensor (in particular it can happen that the sensor, or more accurately, the coils contained therein, cannot be placed as close to the magnetic field source as desired).

So far, no method of eliminating the said problems, at any rate no method that does not involve unreasonable effort, has been found.

### SUMMARY OF THE INVENTION

The present invention is therefore based on the problem of developing the device and the method defined above such that devices of this kind can be more versatile in use.

This problem is solved in accordance with the invention by a device which is characterised in that one or more further components of the electrical circuit are arranged on the side of the electrically conductive structure facing the carrier element.

Such a device consisting of "further components" of the electrical circuit enables the second contact points mentioned above, normally formed by pads, to be replaced by other connecting means, such as, for example, by electrical connectors or by contact elements

suitable for soldering the arrangement onto an electrical printed circuit board, such as contact pins for example; these connecting means can be arranged independently of the position of the remainder of the electrical circuit at any desired points within the arrangement and can consequently be contactable, for example, even from the underside of the carrier element.

5

Even inductive sensors or other electrical circuits that could not previously be produced using the thin-film technique, or could only be produced with constraints, can now be produced using the thin-film technique.

10

Moreover, a device constructed as claimed can also be of smaller and more compact construction than is the case with conventional arrangements.

15

Specifically, the said connecting means can be constructed so that they can be connected directly, that is, without diversion via input and/or output terminals provided in a housing of the arrangement, to other components of the system containing the arrangement, whereby the provision of the input and/or output terminals and of the housing or housing part carrying them can be omitted. Moreover, electrical components that were previously arranged on the electrically conductive structure on the side thereof remote from the carrier element can also be shifted into the carrier element, whereby the area of the arrangement can be reduced.

20

A method according to the invention is characterised by the steps:

25

- application of the electrically conductive structure to a temporary substrate,
- mounting further components of the electrical circuit on the electrically conductive structure,
- applying a composition forming the carrier element to the side of the temporary substrate carrying the said circuit parts, and
- removal of the temporary substrate,

30

and represents an especially simple option for manufacturing a device of the present invention.

Advantageous further developments of the invention can be derived from the

following description and the Figures.

### BRIEF DESCRIPTION OF THE DRAWINGS

The invention is explained in more detail hereinafter on the basis of exemplary  
5 embodiments and with reference to the drawings, in which:

Figure 1 shows the construction of an exemplary embodiment of a device according  
to the invention, and

Figures 2A to 2C show different stages in the manufacture of the device shown in  
Figure 1.

### DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The device described in the following concerns an inductive sensor. It should be  
pointed out at this juncture, however, that the characteristics of the arrangement described in  
detail below can be used also in any other arrangements that comprise an electrical circuit  
15 carried by a carrier element with an electrically conductive structure provided on a surface of  
the carrier element.

The device of which the construction and manufacture are described in detail below is  
shown in Figure 1. It consists of:

- 20 – a plastics material carrier element T, which in the example under consideration has  
a thickness between 1 mm and 2 mm, but can also be thicker or thinner as  
required,
- applied to the carrier element T, or more accurately to the surface of a side of the  
carrier element T, an electrically conductive structure formed by a single-layer or  
multi-layer thin film TF and forming one or more coils,
- two electrical connectors C1 and C2 in the form of SMT components, which are  
soldered onto the electrically conductive structure and are so embedded in the  
carrier element T that they are contactable from the side of the carrier element  
remote from the electrically conductive structure.

Such a device can be manufactured especially easily when the procedure as described  
below with reference to Figures 2A to 2C is followed.

The starting point of the manufacture is a temporary substrate TS, which in the example under consideration is a plate-shaped element consisting of metal. A single-layer or multi-layer thin film TF is applied to this temporary substrate TS; if the thin film is a multi-layer thin film, the individual thin film layers are applied in a sequence that is opposite to the sequence in which the layers are arranged on the carrier element T of the finished component (shown in Figure 1). The resulting intermediate product is illustrated in Figure 2A.

The electrical connectors C1 and C2, which, as already mentioned above, are SMT components, are then soldered onto specifically provided contact points of the electrically conductive structure formed by the thin film TF. The resulting intermediate product is illustrated in Figure 2B.

The temporary substrate TS, or more accurately, the side of the same carrying the electrically conductive structure, and parts of the electrical connectors C1 and C2 are subsequently potted or encapsulated in a composition that in the cured state forms the carrier element T of the finished component (shown in Figure 1). The resulting intermediate product is illustrated in Figure 2C.

The temporary substrate TS is then removed (for example, by etching the same away). This results in the finished component shown in Figure 1.

The device shown in Figure 1 can also in principle be manufactured in other ways and its method of manufacture is not limited to the one described here.

Regardless of its manner of manufacture, the device shown in Figure 1 has the advantages:

- that its construction is better adaptable to particular conditions (it is more versatile in use), and
- that it can be made smaller and more compact than is the case with conventional devices of this kind.

It will be understood that these advantages can also be achieved when:

- the electrically conductive structure TF is formed not, as in the example under consideration, by a thin-film structure, but using other materials and/or techniques, for example, by a thick-film structure, by electrically conductive foils (laminated onto the temporary substrate), a small printed circuit board or multi-layer ceramics,
- additional components or components other than coils, or simply electrical strip conductors, are realised by the electrically conductive structure TF,
- in addition or as an alternative to the electrical connectors, further or other connecting devices for connecting the arrangement to other components of the system containing the arrangement, for example, pins that can be used for soldering the arrangement onto an electrical printed circuit board, are mounted on the side of the electrically conductive structure TF facing the carrier element T,
- in addition or as an alternative to the connecting devices, other components, such as, for example, resistors, capacitors, coils, transistors, semiconductor chips etc., are mounted on the side of the electrically conductive structure TF facing the carrier element T,
- the components of the electrical circuit mounted on the side of the electrically conductive structure TF facing the carrier element T are constructed and/or are mounted in a manner other than described above, and/or
- the temporary substrate TS consists of a material other than metal, for example, glass or ceramics.

A device constructed as described, irrespective of the details of practical realisation and manufacture thereof, can be constructed to be smaller and more compact and is more versatile in use than is the case with the conventional device of this kind. In addition when the described manufacturing process is used, the arrangement can also be manufactured very easily.

Sub A2 → It will be understood by those skilled in the art that the present invention is not limited to the embodiments shown and that many additions and modifications are possible without departing from the scope of the present invention as defined in the appending claims.
